The spectra observed in ARPES measurements are examined together with the resonance peak observed in neutron scatterings, based on the slave-boson approach to $t - t' - J$ model. We show that the peak/dip/hump features arise from the scattering of electrons by collective spin excitations which, at the same time, give rise to the neutron resonance mode. The doping dependences and the dispersions of the peak/dip/hump positions are shown to be consistent with experiments. Our results indicate that recently observed $\cos(6\theta)$ deviation from the pure d -wave also result from the renormalization by spin fluctuations.

Both angle resolved photoemission spectroscopy (ARPES) and neutron scattering experiments have played important roles in the studies of high- T_c superconductors. It has been shown by ARPES that the spectral lineshape possesses a peak/dip/hump structure in the superconducting(SC) state [1,2]. The anomalous momentum, temperature and doping dependences of the spectral lineshape suggest that electrons are strongly coupled to collective excitations centered at (π, π) and these collective excitations are related to the pairing interaction [3]. On the other hand, the most prominent feature of the spin susceptibility observed in neutron scattering studies is the sharp resonance peak at (π, π) in the superconducting or pseudogap states [4–6]. It has been speculated [3,7], from a comparison of these two kinds of experimental data, that the collective excitations are the resonance modes in the neutron scattering experiments. This idea has been further explored qualitatively in a phenomenological spin-fermion model [8], in which the resonance mode is identified as the propagating collective spin excitations and the scattering of electrons by these spin modes gives rise to the anomalous spectral lineshape. Using the slave-boson theory for the $t - t' - J$ model, Brinckmann and Lee [9] have investigated the spin resonance and its evolution with doping.

Recent ARPES study reveals the specular dependences of the peak, dip and hump energies with doping [10]. Furthermore, a small $\cos(6\theta)$ (θ is the Fermi surface angle) deviation from the pure d -wave structure is observed [11]. These results and their correlation with the mode energy

inferred from neutron data are the essential ingredient for a consistent picture of the ARPES lineshape and the neutron data. In this paper, we examine these issues and show that they can be quantitatively reproduced based on the slave-boson approach to the 2D $t - t' - J$ model.

The model reads,

$$H = - \sum_{\langle ij \rangle, \sigma} t c_{i\sigma}^+ c_{j\sigma} - \sum_{\langle ij \rangle', \sigma} t' c_{i\sigma}^+ c_{j\sigma} + \frac{J}{2} \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j, \quad (1)$$

where $\langle ij \rangle$ denotes the nearest-neighbor (n.n.) bond and $\langle ij \rangle'$ the next n.n. bond. In the slave-boson method, the physical electron operators $c_{i\sigma}$ are expressed by slave bosons b_i carrying the charge and fermions $f_{i\sigma}$ representing the spin; $c_{i\sigma} = b_i^+ f_{i\sigma}$. We consider the d -wave SC state with the order parameters $\Delta_{ij} = \langle f_{i\uparrow} f_{j\downarrow} - f_{i\downarrow} f_{j\uparrow} \rangle$ and $\chi_{ij} = \sum_{\sigma} \langle f_{i\sigma}^+ f_{j\sigma} \rangle$, in which bosons condense $b_i \rightarrow \langle b_i \rangle = \sqrt{\delta}$ (δ is the hole concentration) [12]. Then, the mean-field Hamiltonian of Eq.(1) is,

$$H_m = \sum_{k\sigma} \epsilon_k f_{k\sigma}^+ f_{k\sigma} - \sum_k \Delta_k (f_{k\uparrow}^+ f_{-k\downarrow} + c.c.) + 2NJ'(\chi_0^2 + \Delta_0^2), \quad (2)$$

where the dispersion for fermions $\epsilon_k = -2(\delta t + J'\chi_0)[\cos(k_x) + \cos(k_y)] - 4\delta t' \cos(k_x) \cos(k_y) - \mu$, and the gap $\Delta(k) = 2J'\Delta_0[\cos(k_x) - \cos(k_y)]$, with $J' = 3J/8$. The mean-field parameters χ_0 , Δ_0 and the chemical potential μ for different doping δ are obtained from a self-consistent calculation [12].

In the above mean-field calculation, we have set $\langle \mathbf{S}_i \rangle = 0$ [12]. In order to consider the response to external magnetic and electric fields, we include the antiferromagnetic (AF) fluctuation by writing $H = H_m + H'$, where $H' = H - H_m$, and treating H' as a perturbation to H_m . In the Hartree-Fock approximation, this reproduces the mean-field results [13]. To investigate the AF fluctuations, we consider the scattering of electrons off spin fluctuations in H' . As a first step, we calculate the spin susceptibility in the random-phase approximation (RPA) as shown in Fig.1(a),

$$\chi(\mathbf{q}, \omega) = \chi_0(\mathbf{q}, \omega) / [1 + \alpha J(\mathbf{q}) \chi_0(\mathbf{q}, \omega)]. \quad (3)$$

Here $J(\mathbf{q}) = J(\cos q_x + \cos q_y)$ and $\chi_0(\mathbf{q}, \omega)$ is the unperturbed spin susceptibility which is calculated from the fermionic bubbles representing particle-hole excitations. Following Ref. [9], we choose $\alpha = 0.34$ in order to set the AF instability at $\delta = 0.02$, which is the experimental observed value. This is the only adjusted parameter throughout the paper. The fermionic self-energy is obtained from the lowest-order contribution of the scatterings of fermions off spin fluctuations. In the SC state, there are two different self-energies Σ_s and Σ_w as shown in Fig.1(b) and (c), which renormalize the fermionic dispersion and the SC gap, respectively. In the previous study [8], only Σ_s is included in their calculations. We will show that the inclusion of Σ_w lead the otherwise flat doping dependence of the ARPES peak to be consistent with experiments. The fermionic Green's function is calculated by $G_f(\mathbf{k}, \omega) = [G_{f0}^{-1}(\mathbf{k}, \omega) + (\Delta_k + \Sigma_w)^2 G_{f0}^{-1}(-\mathbf{k}, -\omega)]^{-1}$ with $G_{f0}(\mathbf{k}, \omega) = [i\omega - \epsilon_k - \Sigma_s(\mathbf{k}, \omega)]^{-1}$. In the SC state, bosons condense and the physical electron Green's function can be approximated by $G(\mathbf{k}, \omega) \approx \delta G_f(\mathbf{q}, \omega)$. Then, the spectral function of electrons is calculated from $A(\mathbf{k}, \omega) = -(1/\pi)\text{Im}G(\mathbf{k}, \omega)$. Numerical calculations are performed at low temperature $T = 0.005J$, with $t = 2J$, $t' = -0.45t$, and $J = 0.13\text{eV}$.

We first analyze the imaginary part of the spin susceptibilities at $\mathbf{Q} = (\pi, \pi)$. It develops sharp resonance peaks for various doping densities. This result has been reported in Ref. [9]. In the framework of the d -wave BCS theory, the origin of these peaks has been discussed [9,14,15]. Essentially the peak arises from a collective spin excitation mode corresponding to $1 + \alpha J(\mathbf{Q})\text{Re}\chi_0(\mathbf{Q}, \omega) = 0$ and negligibly small $\text{Im}\chi_0(\mathbf{Q}, \omega)$. It is due to a step-like rise of $\text{Im}\chi_0$ at its gap edge and then a logarithmic singularity in $\text{Re}\chi_0$ via the Kramers-Kronig relation. This singularity shifts downward the collective mode energy and leads it to situate in the spin gap, so no damping is expected for the mode. The step-like rise in $\text{Im}\chi_0$ arises from the flat band (extended van Hove singularity) which is observed near $(\pi, 0)$ [16] and the property that $\Delta_{\mathbf{k}+\mathbf{Q}} = -\Delta_{\mathbf{k}}$ for transition momentum $\mathbf{Q}$ due to the d -wave gap symmetry [15].

The lineshape $A(\mathbf{q}, \omega)f(\omega)$ ($f(\omega)$ is the Fermi distribution function) of electrons coming from the scatterings by spin fluctuations for doping $\delta = 0.12$ are shown in Fig.2. The results are plotted for several wavevectors $k = (\pi, 0), (\pi, 0.15\pi), \dots$, down to $(\pi, 0.5\pi)$. Clear peak/dip/hump structures are present at and near $(\pi, 0)$. In order to understand the origin of the peak/dip/hump structure, we plot the self-energy Σ_s [Σ_w is qualitatively similar to Σ_s] at the Fermi wavevector k_F for doping $\delta = 0.12$ in the inset of Fig.2. The solid line denotes its real part Σ'_s , while the dashed line its imaginary part Σ''_s . The corresponding lineshape at k_F is expressed by the line with open squares in the main panel. Due to the

coupling to the spin resonance mode, the whole structure of the self-energy Σ_s is very similar to that of the unperturbed spin susceptibility χ_0 (for a comparison, see Fig.2 in Ref. [15]). When frequency $|\omega|$ is below about $0.5J$, Σ''_s is equal to zero. Above $0.5J$, a step-like rise can be seen and is followed by a decrease. Consequently, Σ'_s has a peak at about the center of the step-like rise of Σ''_s . The quasiparticle energy is given by the pole of the Green's function, which is the solution ω of the equation $P(k_F, \omega) = \text{Re}[(\omega - \Sigma_s(k_F, \omega))^2 - (\Delta_{k_F} + \Sigma_w(k_F, \omega))^2] = 0$. We also show $P(k_F, \omega)$ (dotted line) in the inset of Fig.2. The lowest binding-energy solution of the pole equation $P(k_F, \omega) = 0$ is $\omega = -0.42J$. Meanwhile, the damping of this mode which is proportional to Σ''_s and Σ''_w approaches to zero. Therefore, it gives rise to a quasiparticle mode which is denoted by the sharp low binding-energy peak in the lineshape shown in Fig.2. As $|\omega|$ increases further, the pole equation does not satisfy anymore. Near the end of the step-like rise in Σ''_s , $P(k_F, \omega)$ reaches its local maximum, meanwhile the imaginary part of the self-energy is also near its maximum, therefore a dip appears. It indicates that the dip is caused by the step-like rise in the imaginary part of the self energy. After the dip, $P(k_F, \omega)$ decreases with $|\omega|$ and near $\omega = -1.0J$, it reaches a local minimum. This leads to the broad higher binding-energy hump.

We now discuss the dispersion of the hump/dip/peak structure. At the momentum range below and slightly above the Fermi wavevector $(\pi, 0.15\pi)$, the low binding-energy peak nearly does not disperse with k . Above $(\pi, 0.3\pi)$, the peak starts to move to higher binding-energy but cannot move further than that dip seen around k_F . Then, it disappears gradually with the further increasing of k , due to the unavailable quasiparticle states above the Fermi surface at low temperatures. As a result, the dip also disappears gradually. These behaviors were observed in experiments [10]. The position of the peak determines the normalized gap size due to spin fluctuations. In Fig.3, we show a typical dependence of the renormalized gap magnitude on the Fermi surface angle θ , which is the angle between k_F and k_x . In general, the next order deviation from the d -wave starts from $\cos(6\theta)$ and can be described by the form $\Delta(\theta) = \Delta_1 \cos(2\theta) + \Delta_2 \cos(6\theta)$. However, our results indicate that the best fit is $\Delta(\theta) = \Delta_{\max}[B \cos(2\theta) + (1 - B) \cos(6\theta)]$ with B being around 0.88-0.94. This particular form was also used in Ref. [11] to fit their ARPES data with roughly the same range of B .

In Fig.4(a), we show the doping dependence of the positions of the hump and the peak, and compare our results with the experiment [10]. One can see that our result for the peak is in reasonably good agreement with the experiment. We note that, if we just include the self-energy Σ_s in our calculation as was done in Ref. [8], a doping independence for the peak positions is obtained. Hence the renormalization of the gap by including Σ_w is

important. The magnitude of the position of the hump and its trend with the doping variation are also consistent with the experiment. However, the slope of the curve of hump versus hole density is flatter than the experimental result. Considering that all parameters in our calculations are chosen according to the well-known values and the only adjusted parameter α is fixed by the experimental observation on AF instability, these results are quite satisfactory. The dependence of the ratio between the hump and peak energy at $(\pi, 0)$ on doping concentrations is shown in Fig.4(b). A flat variation for a wide doping level is seen. This result again agrees with the experiment [10].

An important quantity addressed in the ARPES experiments is the peak-dip separation, which is shown to be close to the mode energy of the neutron peak [10]. From a comparison of Fig.2 in Ref. [9] and Fig.3, one can see that the peak-dip separation in our calculations is lower than the neutron peak. However, we would like to point out that this separation is sensitive to the experimental energy resolution simulated to be $\Gamma = 0.02J$ here. When Γ increases, the self-energy Σ_s'' decreases and the quasiparticle peak broads, consequently the peak-dip separation increases. However the position of the neutron scattering peak does not change for different Γ , it just becomes broad. So, this comparison is also sensitive to Γ . But, as noted above, the dip stems from the step-like edge in Σ_s'' which is in turn caused by the coupling to the collective spin mode. On the other hand, this spin resonance mode also arises from the step-like edge in $\text{Im}\chi_0$ which is due to the extended van Hove singularity near $(\pi, 0)$ and the d -wave symmetry. Therefore, an intimate relation between them is suggested. Thus, our result seems to provide a consistent picture for the spin resonance peak and the hump/dip/peak structure based on the spin excitations in a d -wave superconductor.

Recently, P.J.White *et al.* [17] have investigated the effect of nonmagnetic Zn impurities on the lineshape of $\text{Bi}_2\text{Sr}_2\text{Ca}(\text{Cu}_{1-x}\text{Zn}_x)\text{O}_{8+\delta}$ by ARPES experiment. They found that the dip is diminished with Zn doping. According to the previous studies by one of the authors (Li) [15], Zn doping will wash out the van Hove singularity and cause the decays of quasiparticle states. So, the enhancement in $\text{Re}\chi_0$ and the step-like rise in $\text{Im}\chi_0$ will be suppressed. As a result, no clear resonance neutron peak appears at certain Zn doping concentration [15]. Because the dip is suggested to come from the coupling to the spin resonance mode here, the disappearance of the dip upon Zn doping may be naturally explained in the present framework.

It is quite encouraging that our results fits various kinds of ARPES and neutron scattering data with correct trend and reasonable magnitude. There is only one adjustable parameter which is fixed by the experimentally observed AF instability. Therefore, our investigation represents a natural extension to the work of Brinckmann

and Lee [9], which addressed the doping dependence of the resonance peak in neutron scatterings. In addition, in comparison to the qualitative study by Abanov and Chubukov [8], our study further furnishes a quantitative basis.

In summary, based on the slave-boson approach to the $t - t' - J$ model, we show that the anomalous peak/dip/hump structure observed in the ARPES experiments arises from the coupling of quasiparticle to the collective spin excitations which gives rise to the resonance peak in the neutron scattering experiments. Our investigation seems to give a consistent explanation for the resonance neutron peak and the ARPES spectra based on the spin excitations in a d -wave superconductor.
